**Aspergillus fumigatus**

*Aspergillus fumigatus* is an **opportunistic** fungal pathogen. The spores of this fungus, called **conidia**, are found widely in the environment and it is thought that we inhale several conidia daily. When we inhale conidia, resident immune cells in our lungs **phagocytose** and destroy them—preventing them from causing an infection. **Alveolar macrophages** in the lung are the primary line of defence against conidia.

As with many fungal pathogens, when the immune system becomes impaired we become highly susceptible to *A. fumigatus* infection. *A. fumigatus* causes a wide range of infections, including chronic lung disease (chronic pulmonary aspergillosis) and life-threatening systemic infection that can involve multiple organs (invasive aspergillosis). *A. fumigatus* is a major concern for patients undergoing haematopoetic stem cell transplantation, patients with chronic neutropenia (a reduction in circulating neutrophils) and patients receiving high-doses of steroids.

If the immune system is ill-equipped to deal with inhaled conidia, these spores start to swell and form filamentous forms called **germ tubes** (short tubes) and **hyphae** (long tubes). These elongated cells can penetrate host cells and cause damage. Our immune system also reacts more violently to these forms of the fungus, which stimulate production of **pro-inflammatory cytokines** and may contribute towards immunopathology.

**Immunity to *A. fumigatus***

When conidia swell and start forming germ tubes/hyphae, the fungal cell wall starts to change. This results in exposure of previously hidden **pathogen-associated molecular patterns** (PAMPs); key molecules recognized by receptors of the innate immune system (pattern recognition receptors, PRRs).

For example, β-**glucans** primarily make up the cell walls of fungal hyphae but are shielded from the immune system in conidia by a proteinaceous layer. β-glucans are recognised by the PRR, **Dectin-1**, expressed by myeloid cells, which initiates inflammatory responses to most types of fungi (Figure 1). In *A. fumigatus* infections, Dectin-1 mediates uptake and killing of *A. fumigatus*. Humans with a point mutation in the Dectin-1 gene are highly susceptible to *A. fumigatus* infection following transplants and this is cited as a risk factor.

Lastly, epithelial cells which line the lung can also protect against *A. fumigatus* invasion. Epithelial cells also express PRRs, including the recently characterised MelLec. MelLec binds to melanin, which is expressed by conidia (and thus appear green/black; Figure 2). MelLec is an important receptor for protecting against *A. fumigatus* infections, and similar to Dectin-1, point mutations in this gene in humans are a risk factor for invasive *A. fumigatus* infections.
